ABSTRACT

Measurements of the intensity of the cosmic X-ray background (XRB) carried out over small solid angles are subject to spatial variations due to the discrete nature of the XRB. This cosmic variance can account for the dispersion of XRB intensity values found within the *ASCA*, *BeppoSAX* and *ROSAT* missions separately. However there are differences among the values obtained in the different missions which are not due to spatial fluctuations but, more likely, to systematic cross-calibration errors. Prompted by recent work which shows that *ROSAT* PSPC has calibration differences with all the other missions, we compute a bayesian estimate for the XRB intensity at 1 keV of $10.0^{+0.6}_{-0.9} \text{ keV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ keV}^{-1}$ (90 per cent confidence errors) using the *ASCA* and *BeppoSAX* data points. However, this value is still significantly larger than the *HEAO* – 1 intensity measured over many thousands of square degrees ($8 \text{ keV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ keV}^{-1}$).

Key words: Cosmology: diffuse radiation – X-rays: general.

1 INTRODUCTION

Most of the X-ray background (XRB) above photon energies of a few keV is known to be extragalactic in origin (see, e.g. reviews by Boldt 1987 and Fabian & Barcons 1992). Its spectrum was well measured by the *HEAO* – 1 A2 experiment in the 3–50 keV energy range (Marshall et al 1980), where it fits a thermal bremsstrahlung model with a temperature $kT \approx 40 \text{ keV}$. An overall fit to the XRB spectrum from 3 keV to 10 MeV was presented by Gruber (1992) based on data from the A2 and A4 experiments on board *HEAO* – 1, which showed an extrapolated intensity at 1 keV of $\approx 8 \text{ keV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ keV}^{-1}$.

More recently, measurements of the XRB spectrum and intensity at photon energies $< 10 \text{ keV}$ have been obtained with the use of imaging instruments. Using *ASCA* data, Gendreau et al (1995) confirmed that the thermal bremsstrahlung shape (which at photon energies below $\sim 20 \text{ keV}$ can be approximated by a power law with energy spectral index $\alpha \sim 0.37$) provides a good fit to the XRB spectrum down to about 1 keV. Vecchi et al (1999) used the LECS and MECS instruments on board *BeppoSAX* in the 1–8 keV band to confirm that the XRB spectrum is consistent with a power law with $\alpha \sim 0.4$.

ROSAT PSPC observations have also provided data on the spectrum of the extragalactic XRB. Hasinger (1992) found a very steep spectrum for the XRB below 2 keV ($\alpha \sim 1$). However, shadowing experiments with *ROSAT* have provided the more stringent upper limits to the slope of

the extragalactic XRB at soft X-ray energies ($\alpha < 0.7$, Barber & Warwick 1994). The relative steepness of the *ROSAT* spectra with respect to many other instruments has been studied in detail by Iwasawa, Fabian & Nandra (1999). The fact that the spectral shape of the same sources is usually consistent in observations of many instruments with the exception of *ROSAT* (which usually finds steeper spectra) is highly suggestive of a calibration mismatch which will certainly affect the XRB spectrum as well.

The normalisation of the extragalactic XRB (that we parametrise as the XRB intensity I_{XRB} at 1 keV in units of $\text{keV cm}^{-2} \text{ s}^{-1} \text{ sr}^{-1} \text{ keV}^{-1}$) remains uncertain. The Marshall et al (1980) measurement is the most robust result as it was performed over a very large solid angle ($\sim 10^4 \text{ deg}^2$) with instrumentation especially designed to subtract efficiently and accurately the particle background. The XRB intensity measured by the imaging instruments on board *ASCA*, *BeppoSAX* and *ROSAT* invariably yield higher values which are often statistically discrepant among them.

In this paper we point out that the discrete nature of the XRB introduces a cosmic variance in its intensity which is large for observations carried out over small solid angles. This cosmic variance is just the confusion noise caused by unresolved or non removed sources in the images (Scheuer 1974, Barcons 1992). We find variations of the order of 10 per cent for solid angles under 1 deg^2 and therefore cosmic variance often dominates over the statistical uncertainties quoted in the various estimates of the XRB intensity. Once this is included, we combine individual measurements of the

Table 1. Measurements of the XRB intensity at 1 keV carried out with imaging instruments. Ω_i is the solid angle covered, I_i the measured intensity, σ_i the 1-sigma statistical uncertainty and Σ_i the 1-sigma uncertainty derived when statistical and cosmic variances are included.

XRB to compute bayesian estimates of the overall XRB intensity. We find that measurements carried out within the same mission are brought to consistency by cosmic variance, but that systematic differences between different missions remain.

2 THE COSMIC VARIANCE

Table 1 lists the XRB intensity measurements that we have used. In particular and for each particular datum we list the measured intensity at 1 keV I_i , the quoted statistical 1-sigma error σ_i (converted from 90 per cent errors) and the solid angle covered Ω_i . It is clear that the variations between different measurements carried out within the same mission are often significant, if the statistical errors σ_i are used to assess the significance. In what follows we compute the additional uncertainty introduced by the cosmic variance.

If the true average XRB intensity is I_{XRB} then we want to compute the probability density function $P_i(I|I_{XRB})$ of obtaining an intensity I in a measurement over a solid angle Ω_i with a statistical error σ_i . This is computed by first convolving the confusion noise distribution with the statistical noise distribution (which we assume to be gaussian) and later shifting the resulting distribution to have a mean value I_{XRB} . This shift can be attributed to the behaviour of the source counts in the very faint regime, which would not affect the shape of the distribution. Assuming a top-hat beam (which is appropriate for our purposes), the confusion noise distribution can be expressed as (Barcons 1992)

$$P_i^{conf}(I) = \int d\omega e^{-2\pi i \omega I} \exp(\Omega_i \int dS N(S) [e^{2\pi i \omega S} - 1]) \quad (1)$$

where $N(S)$ is the number of sources per unit solid angle and unit flux which in the range were we shall use it ($S \sim 10^{-13} - 10^{-12}$ erg cm⁻² s⁻¹) can be approximated as euclidean

$$N(S) = \frac{3}{2} \frac{K}{S_0} \left(\frac{S}{S_0} \right)^{-5/2}, \quad (2)$$

where we choose $S_0 = 10^{-14}$ erg cm⁻² s⁻¹ and then K is the source density, extrapolated with the same euclidean

law, at a flux limit 10^{-14} erg cm⁻² s⁻¹. Indeed, the value of K depends on the energy band used for the observations. For the ‘hard’ X-ray measurements (*ASCA* and *Bep-poSAX*) we assume an extrapolation of the Piccinotti et al (1982) source counts, now confirmed down to fluxes below 10^{-13} erg cm⁻² s⁻¹ (Cagnoni, Della Ceca & Maccaro 1998, Gendreau et al 1998). This gives $K \approx 300$ deg⁻². For the ‘soft’ X-ray measurements we use the *ROSAT* normalisation $K \approx 150$ deg⁻² (Hasinger et al 1993, Branduardi-Raymont et al 1994). In modelling the confusion noise distribution for the various measurements of the XRB intensity, we have taken into account the possible excision of bright foreground sources by applying the corresponding cutoff in the flux integral of eqn. (1). This really only applies to the Chen et al (1996) *ROSAT* measurement where sources brighter than 3.4×10^{-14} erg cm⁻² s⁻¹ were excluded. For the remaining measurements we have assumed that the sources in the Piccinotti et al (1982) catalogue had been avoided and therefore we applied a cutoff at a flux of 2-10 keV of 3×10^{-11} erg cm⁻² s⁻¹.

Equation (1) ignores clustering of the XRB sources. Indeed clustering broadens the distribution of intensities with respect to a uniform distribution (Barcons 1992). From Barcons, Fabian & Carrera (1998) we see that for angular scales of the order of ~ 1 deg², excess fluctuations due to clustering amount to $\sim 0.5 - 1.2\%$, which implies a correction of the order of $\sim 10\%$ (at most) to the broadening computed by eq. (1). The relative amplitude of the clustering correction stays approximately constant when going to slightly smaller scales and decreases slowly when the small-scale declining part of the power spectrum of the fluctuations is reached. Given the smallness of this effect and the uncertainties in the modelling of the source clustering and its evolution we decided to ignore this small effect.

Convolving eqn. 1 with a gaussian of dispersion σ_i and shifting the mean to a value I_{XRB} gives the function $P_i(I|I_{XRB})$ where now we express I and I_{XRB} as monochromatic intensities at 1 keV in units of keV cm⁻² s⁻¹ sr⁻¹ keV⁻¹. For the conversion between monochromatic intensity and broad-band flux S per unit solid angle in a given energy band we use an XRB spectral

Figure 1. Bayesian density functions of the XRB intensity for the measurements obtained with *ASCA*, *BeppoSAX* and *ROSAT*. Individual measurements are shown on the same curves as filled points (*ASCA*), asterisks (*BeppoSAX*) and squares (*ROSAT*). The HEAO-1 point is also shown as a vertical arrow. The top panel shows the bayesian distributions for each mission separately, the mid panel for the 3 missions all together and the bottom panel for the *ASCA* and *BeppoSAX* missions together.

shape with $\alpha = 0.4$ for the ‘hard’ instruments and $\alpha = 0.7$ for the ‘soft’ instruments which result in

$$I(\text{keV cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{keV}^{-1}) = \frac{S}{S_0} \Omega(\text{deg}^2)^{-1} \Delta^{-1} \quad (3)$$

where $\Delta \approx 200$ if the flux is in the 2-10 keV band and $\Delta \approx 70$ if the flux is in the 0.5-2 keV band.

Typically, the curves including the cosmic variance are much broader than the the statistical error. To illustrate this, Table 1 also lists the dispersion Σ_i obtained via a gaussian fit to $P_i(I|I_{XRB})$ (which accounts for both the statistical and the cosmic variance) for comparison with the statistical dispersion σ_i .

We now use these distributions to compute bayesian estimates of the true XRB intensity I_{XRB} . We assume an *a priori* distribution which is uniform over a sufficiently wide range of values of I_{XRB} (5 to $16 \text{ keV cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{keV}^{-1}$). The probability density function for I_{XRB} given a set of data is (Press 1989)

$$f(I_{XRB}) = \frac{\prod_i P_i(I_i|I_{XRB})}{\int dI'_{XRB} \prod_i P_i(I_i|I'_{XRB})} \quad (4)$$

where the products extend to the data points under consideration. In what follows, our I_{XRB} estimates correspond to the maximum of that function, which we also use to derive 90% confidence intervals.

3 THE INTENSITY OF THE XRB

We first compute $f(I_{XRB})$ for the measurements obtained within each imaging X-ray mission separately. The results are shown in Fig. 1 where it can be seen that the various measurements with the same instrument are consistent when cosmic variance is taken into account. In particular the variety of *ASCA* values which have been obtained with both the SIS and GIS instruments at different epochs, does not call for extra systematic effects. The same comment applies to the *ROSAT* data points, as none of them is completely out of the distribution expected in terms of cosmic variance and statistical uncertainties, in spite of the fact that these intensities have been obtained with different PSPCs and/or different gains. The corresponding estimates of the XRB intensity are $9.8^{+0.7}_{-1.0}$, $11.1^{+1.0}_{-2.3}$ and $12.7^{+0.9}_{-1.9} \text{ keV cm}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{keV}^{-1}$ (90 per cent errors) for *ASCA*, *BeppoSAX* and *ROSAT* respectively.

Although there is considerable overlap between the distributions corresponding to the three missions, there are obvious systematic differences. To illustrate this we combine all the data points with the use of eqn. 4 (see Fig. 1). The fact that there are points which obviously fall outside the distribution confirms the presence of systematic differences between the missions. Indeed the largest differences occur between *ASCA* and *ROSAT* amounting to ~ 30 per cent.

Cross-calibration mismatches between missions have been reported by various authors, in particular between *ROSAT* and *ASCA* (e.g., Yaqoob et al 1994, Allen & Fabian 1997). Iwasawa et al (1999) addressed this point with detail, motivated by simultaneous *ROSAT* and *ASCA* observations of the Seyfert galaxy NGC 5548. They find that the *ROSAT* PSPC spectrum is $\Delta\alpha \sim 0.4$ steeper than the simultaneous *ASCA* spectrum over a similar energy band. Iwasawa et al (1999) also comment on the fact that these calibration mismatches do not occur between *ASCA* and any other missions, which find similar spectral shapes for a variety of objects observed.

A further complication in the combination of XRB data from various missions is the different influence of the Galaxy. The main *ASCA* (Gendreau et al 1995) and *BeppoSAX*

(Vechhi et al 1999) measurements of the XRB intensity only used events above 1 keV, where the contribution from the Galaxy is ~ 1 per cent or less for these instruments. However, in the Hasinger (1992) *ROSAT* estimate, the whole 0.1-2.4 keV band was used to extract both the extragalactic and local components. For example, more than 30 per cent of the counts above 0.5 keV are of galactic origin. Although the influence of the Galaxy on the determination of I_{XRB} is uncertain in the *ROSAT* data, it is likely to be more important.

Excluding the *ROSAT* data points, a bayesian estimate of I_{XRB} yields $10.0^{+0.6}_{-0.9}$ keV cm $^{-2}$ s $^{-1}$ sr $^{-1}$ keV $^{-1}$, but the fact that the largest measured intensity is the *BeppoSAX* one is suggestive of residual systematic effects (see again fig. 1). In this case, however, these do not need to be larger than a few per cent.

All of the above estimates give significantly higher values for the XRB intensity than the extrapolated value of the HEAO-1 data. For the *BeppoSAX* and the *ASCA* data, the *HEAO-1* value (8 keV cm $^{-2}$ s $^{-1}$ sr $^{-1}$ keV $^{-1}$) is still marginally consistent with the current modelling in terms of statistical and cosmic variance of the *ASCA* and *BeppoSAX* data. However, this interpretation would mean that the regions of the sky used in the imaging observations are systematically brighter than the average sky sampled by *HEAO-1*. The possibility that the XRB spectrum between 1 and 3 keV is steeper than the assumed $\alpha = 0.37$ (there is a hint of this in the HEAO-1 data, see the mid panel of Fig. 4a in Marshall et al 1980) does not really help to alleviate this mismatch. The reason is that both *ASCA* and *BeppoSAX* measurements are quite sensitive to photon energies ~ 3 keV, where the intensities found are significantly larger than the *HEAO-1* result at the same energy.

4 CONCLUSIONS

Cosmic variance is able to account for the dispersion of the measured values of the extragalactic XRB intensity within the same mission. However, systematic differences remain among different missions, which cannot be understood in terms of spatial fluctuations.

A cross-calibration mismatch between *ROSAT* observations and those from other missions has been reported (Iwasawa et al 1999). But even using the *ASCA* and *BeppoSAX* data only the result ($10.0^{+0.6}_{-0.9}$ keV cm $^{-2}$ s $^{-1}$ sr $^{-1}$ keV $^{-1}$) is higher than the XRB intensity at 1 keV extrapolated from the HEAO-1 data at photon energies above 3 keV. A steepening of the XRB spectrum at energies below 3 keV does not really help as both *ASCA* and *BeppoSAX* are sensitive to energies ~ 3 keV and above where the mismatch persists. The only conclusion we can reach is that although internal calibration uncertainties in each mission amount to probably less than 10 per cent, the cross-calibration among them has still large residual errors, preventing a more precise determination of the XRB intensity.

XMM is and will be for many years the most sensitive X-ray imaging facility over the 0.1-10 keV energy band, providing also moderate spectral resolution. Over 1 year, XMM will carry out observations of 500-1000 fields of ~ 0.2 deg 2 , so we expect ~ 100 deg 2 to be covered each year. The cosmic variance (roughly scaling as $\Omega^{-1/2}$) will then be small

enough for unambiguous determinations of the XRB spectrum and intensity. If the EPIC instruments can be calibrated to significantly better than 10 per cent, this will certainly solve the issue of the intensity of the XRB.
